In this tutorial, you will learn about the quick sort algorithm and its implementation in Python, Java, C, and C++.

ADVERTISEMENTS

Quicksort is [a sorting algorithm](https://www.programiz.com/dsa/sorting-algorithm) (<https://www.programiz.com/dsa/sorting-algorithm>) based on the **divide and conquer approach** where

1. An array is divided into subarrays by selecting a **pivot element** (element selected from the array).

While dividing the array, the pivot element should be positioned in such a way that elements less than pivot are kept on the left side and elements greater than pivot are on the right side of the pivot.

2. The left and right subarrays are also divided using the same approach. This process continues until each subarray contains a single element.
3. At this point, elements are already sorted. Finally, elements are combined to form a sorted array.

the pivot element.

## 2. Rearrange the Array

Now the elements of the array are rearranged so that elements that are smaller than the pivot are put on the left and the elements greater than the pivot are put on the right.

Put all the smaller elements on the left and greater on the right of pivot element

Here's how we rearrange the array:

1. A pointer is fixed at the pivot element. The pivot element is compared with the elements beginning from the first index.

second pointer

If the element is greater than the pivot element, a second pointer is set for that element.

3. Now, pivot is compared with other elements. If an element smaller than the pivot element is reached, the smaller element is swapped with the greater element found earlier.

Pivot is compared with other elements.

4. Again, the process is repeated to set the next greater element as the second pointer. And, swap it with another smaller element.

5. The process goes on until the second last element is reached.

### 3. Divide Subarrays

Pivot elements are again chosen for the left and the right sub-parts separately. And, **step 2** is repeated.

ADVERTISEMENTS

The subarrays are divided until each subarray is formed of a single element. At this point, the array is already sorted.

```
partition(array, leftmostIndex, rightmostIndex)
  set rightmostIndex as pivotIndex
  storeIndex <- leftmostIndex - 1
  for i <- leftmostIndex + 1 to rightmostIndex
    if element[i] < pivotElement
      swap element[i] and element[storeIndex]
      storeIndex++
  swap pivotElement and element[storeIndex+1]
  return storeIndex + 1
```

This condition leads to the case in which the pivot element lies in an extreme end of the sorted array. One sub-array is always empty and another sub-array contains  $n - 1$  elements. Thus, quicksort is called only on this sub-array.

However, the quicksort algorithm has better performance for scattered pivots.

- **Best Case Complexity [Big-omega]:**  $O(n \log n)$

It occurs when the pivot element is always the middle element or near to the middle element.

- **Average Case Complexity [Big-theta]:**  $O(n \log n)$

It occurs when the above conditions do not occur.

## 2. Space Complexity

The space complexity for quicksort is  $O(\log n)$ .
